# Control 개요 - Model

- Mobile robot error-kinematics in body-frame (local) coordinate

- Where  $V_x$  is longitudinal velocity and  $\omega_z = \frac{R_{wheel}}{R_{robot}} (\omega_R - \omega_L)$ .
- $\omega_R$  and  $\omega_L$  부호: longitudinally forward rotation (+)

# Control 개요 – Control Derivation

- Note that our control inputs are  $\omega_R$  and  $\omega_L$ .
- Since there are no control inputs in our system equation, we take the derivative of  $\dot{e}_y$ , assuming that  $V_x$  is fixed. (Similar to feedback-linearization)

$$\begin{aligned}\ddot{e}_y &= V_x \dot{e}_\psi \\ &= V_x \omega_z\end{aligned}$$

- Take  $\omega_z$  as 
$$\omega_z = \frac{1}{V_x} (-K_d(\dot{y} - \dot{y}_r) - K_p(y - y_r))$$
- Then, its closed-loop dynamics become

$$\begin{aligned}\ddot{e}_y + K_d(\dot{y} - \dot{y}_r) + K_p(y - y_r) \\ = \ddot{e}_y + K_d(\dot{e}_y) + K_p(e_y) \\ = 0\end{aligned}$$

- The closed-loop error dynamics become **2<sup>nd</sup> – order ODE, that you might be very familiar with.**
- Also note that  $\omega_z$  rule is equivalent as the PD control, if we don't have the information of  $\dot{y}_r$ .

# Control 개요 – Problem

1. Assume that we don't want any oscillation in  $e_y$ .  
Then, find gain  $K_p$  and  $K_d$  such that  $e_y$  does not oscillate, with the fastest convergence possible.  
(Hint : Select  $\omega_n$  (natural frequency) on your own. You may need the knowledge of mechanical vibration.)
2. Assume that we have obtained the control gains  $K_p$  and  $K_d$  which guarantee fastest convergence and no oscillation.  
Then, derive the control signals of  $\omega_R$  and  $\omega_L$ .  
(Use any assumption that you might need.)  
(Hint : Do not forget  $V_x$ .)
3. Write the pseudo-code for  $\omega_R$  and  $\omega_L$ .
4. Assume that we want closed-loop system response with designated pole location. Define the pole location yourself and derive the control signal  $\omega_R$  and  $\omega_L$ .
5. Simulate the whole process with Matlab using ODE45.  
(Hint : It is mathematical simulation.)

# Simulation Example

- Consider a system

$$\ddot{x} = -x + 2\dot{x} + u$$

- The state variable is  $x = x_1, \dot{x} = x_2$ , then the state-space equation is

$$\begin{aligned}\dot{x}_1 &= x_2 \\ \dot{x}_2 &= -x_1 + 2\dot{x} + u\end{aligned}$$

- For the pole location to be  $(-1,-1)$ , select control input as

$$u = -4\dot{x}$$

## Main file

```
clear; close all; clc

%%
init = [4,0]';
[t,X] = ode45(@(t,X) system_fun(t,X), [0,10],init, '.');

figure(1)
plot(t,X(:,1)); hold on; plot(t,X(:,2));
legend('x', 'dx');
xlabel('time (s)')
```

## ODE Function file

```
function dX = system_fun(t,X)
    dX = zeros(2,1);
    x = X(1);
    dx = X(2);

    u = -4*dx;

    dX(1) = dx;
    dX(2) = -x + 2*dx + u;
end
```

See matlab ode45 Function user manual for the details.

# System parameter for the problem & Simulation

- $V_x = 0.15$  m/s  
 $R_{wheel} = 0.03$  m,  $R_{robot} = 0.075$  m
- Initial condition of  $y = 0.1, \dot{y} = 0, e_\psi = 0$
- Reference trajectory  $y_r = 0.05 \cos\left(\frac{t}{\pi}\right)$
- Use the control signal  $u = [\omega_R, \omega_L]^T$   
Simulate for 50 seconds
- Use simulation states  $X = [y, \dot{y}, e_\psi]^T$
